METALLICITY

OCTOBER 27, 2010

1. Mixture model

Given n observed $(\frac{\alpha}{\text{Fe}}, \frac{\text{Fe}}{\text{H}})$ metallicities as $\{(x_i, y_i)\}_{i=1}^n$, or as $(\mathbf{x}, \mathbf{y})$, each of which is drawn from one of m known model densities. We model the density of observations using the mixture model

$$f(x, y) = \sum_{j=1}^{m} \pi_j f_j(x, y) \tag{1}$$

where

$$\sum_{j=1}^{m} \pi_j = 1 \qquad \pi_j \geq 0, \quad j = 1, \ldots, m$$

From the summation constraint, $\boldsymbol{\pi}$ has $m - 1$ free parameters:

$$\boldsymbol{\pi} = (\pi_1, \ldots, \pi_{m-1}, 1 - \pi_1 - \ldots - \pi_{m-1})$$

Thus the likelihood of (1) is

$$\begin{aligned} L(\boldsymbol{\pi}) &= \prod_{i=1}^{n} f(x_i, y_i) \\ &= \prod_{i=1}^{n} \Big\{ \sum_{j=1}^{m} \pi_j f_j(x_i, y_i) \Big\} \\ \log L(\boldsymbol{\pi}) &= \sum_{i=1}^{n} \log \Big(\sum_{j=1}^{m} \pi_j f_j(x_i, y_i) \Big) \end{aligned}$$

Maximizing $\log L(\boldsymbol{\pi})$ with respect to $\boldsymbol{\pi}$ will yield $\hat{\boldsymbol{\pi}}_{\text{MLE}}$, but this arduous task can be avoided by adding a latent indicator, z, to the observed data $(\mathbf{x}, \mathbf{y})$, representing the model group from which that observation was generated. Let G_j be the j^{th} model group, and let

$$z_{ij} = \mathbf{1}\big\{(x_i, y_i) \mapsto G_j\big\}$$

The complete data likelihood is defined over the complete data $\big\{(x_i, y_i, \mathbf{z}_i)\big\}_{i=1}^{n}$ as

$$L(\boldsymbol{\pi}) = \prod_{i=1}^{n}\prod_{j=1}^{m}\Big\{f_j(x_i, y_i)\Big\}^{z_{ij}}\pi_j^{z_{ij}}$$

$$\ell(\boldsymbol{\pi}) = \sum_{i=1}^{n}\sum_{j=1}^{m} z_{ij}\log\big\{\pi_j f_j(x_i, y_i)\big\} \tag{2}$$

2. Expectation Maximization

One way to estimate $\boldsymbol{\pi}$ is to use a maximum likelihood estimate, $\hat{\boldsymbol{\pi}}$, computed using expectation maximization. Starting from an initial set of guesses, $\boldsymbol{\pi}^{(0)}$, we iteratively find the expected value of the likelihood, (2), conditional on the data, and then find the $\operatorname{argmax}_{\boldsymbol{\pi}}$ of this expectation. The maximizing value the t^{th} iteration, $\hat{\boldsymbol{\pi}}^{(t)}$, is then used as the starting value for the next run, and we continue until the likelihood changes by less than 10^{-3} over twenty five iterations.

2.1. Expectation step.

Expectation step. First we find the expected value of the log likelihood, (2), conditional on the data. Note that since z_{ij} is an indicator function, its expected value is equal to the probability that data point i comes from model j.

$$\mathrm{E}_{\boldsymbol{\pi}}\Big[\ell(\boldsymbol{\pi})\big|\mathbf{x}, \mathbf{y}\Big] = \sum_{i=1}^{n}\sum_{j=1}^{m}\mathrm{E}_{\boldsymbol{\pi}}\big[z_{ij}|x_i, y_i\big]\big\{\log f_j(x_i, y_i) + \log \pi_j\big\}$$

Since we're ultimately maximizing, the non-constant component is of primary interest, and can be analytically specified by applying Bayes' rule:

$$\begin{aligned}
\mathrm{E}_{\boldsymbol{\pi}}\Big[z_{ij}|x_i, y_i\Big] &= \text{Probability}\Big((x_i, y_i) \mapsto G_j\big|x_i, y_i\Big) \\
&= \Pr_{\boldsymbol{\pi}}(z_{ij}|x_i, y_i) \\
&= \frac{p(x_i, y_i|z_{ij} = 1)p(z_{ij} = 1)}{p(x_i, y_i)}
\end{aligned}$$

Thus the expected value of the indicator variable, z_{ij}, given the data and the parameters, $\boldsymbol{\pi}$, of the data's distribution defined by (1) is

$$\mathrm{E}_{\boldsymbol{\pi}}\Big[z_{ij}|x_i, y_i\Big] = \frac{\pi_j f_j(x_i, y_i)}{\sum_{j=1}^{m} \pi_j f_j(x_i, y_i)} \tag{3}$$

To iteratively evaluate this expectation, we let $w_{ij}^{(t)}$ be (3) at the t^{th} step:

$$w_{ij}^{(t+1)} = \begin{cases} \dfrac{\pi_j^{(t)} f_j(x_i, y_i)}{\displaystyle\sum_{k=1}^{m} \pi_k^{(t)} f_k(x_i, y_i)} & j = 1, \ldots, m-1 \\ \\ 1 - w_{i1} - \ldots - w_{i,m-1} & j = m \end{cases}$$

Since $\boldsymbol{\pi}$ is not defined for the first evaluation, we use a random initialization to generate $\mathbf{w}_j^{(0)}$. Convergence is not sensitive to the choice of values in this case, but may be if the likelihood is riddled with local maxima.

2.2. Maximizing with respect to $\boldsymbol{\pi}$.

$$\begin{aligned} 0 &= \frac{\partial}{\partial \pi_k} \mathrm{E}_{\boldsymbol{\pi}}\Big[\ell(\boldsymbol{\pi})\Big|\mathbf{x}, \mathbf{y}\Big] \\ &= \sum_{i=1}^{n} \Big\{ w_{ij}^{(0)} \frac{1}{\pi_k} - w_{im}^{(0)} \frac{1}{1 - \pi_1 - \ldots - \pi_{m-1}} \Big\}, k = 1, \ldots, m-1 \end{aligned}$$

as $\pi_m = 1 - \pi_1 - \ldots - \pi_{m-1}$.

$$\frac{1}{\pi_1} \sum_{i=1}^{n} w_{i1}^{(0)} = \ldots = \frac{1}{\pi_{m-1}} \sum_{i=1}^{n} w_{i,m-1}^{(0)} = c$$

$$\hat{\pi}_k = \frac{\sum_{i=1}^{n} w_{ik}^{(0)}}{c}$$

$$\pi_j^{(1)} = \frac{\sum_{i=1}^{n} w_{ij}^{(0)}}{n}$$

And in general,

$$\pi_j^{(t+1)} = \frac{\sum_{i=1}^{n} w_{ij}^{(t)}}{n}$$

3. Covariance and correlation of $\hat{\boldsymbol{\pi}}$

The asymptotic covariance matrix of $\hat{\boldsymbol{\pi}}$ can be approximated by the inverse of the observed Fisher information matrix, I.

As $\pi_m = 1 - \sum_{j=1}^{m-1} \pi_j$, there are only $m-1$ free parameters. Thus let $\boldsymbol{\pi}_\times = (\pi_1, \ldots, \pi_{m-1})$. Using $f_{ij} = f_j(x_i, y_i)$ for brevity, the likelihood can then be expressed as:

$$\ell(\boldsymbol{\pi}_\times) = \sum_{i=1}^{n} \log \left\{ \left(\sum_{j=1}^{m-1} \pi_j f_{ij} \right) + (1 - \pi_1, \ldots, \pi_{m-1}) f_{im} \right\} \tag{4}$$

The observed information matrix, I, is the $m-1 \times m-1$ negative hessian of (4), evaluated at the observed data points:

$$I(\boldsymbol{\pi}_\times | \mathbf{x}, \mathbf{y}) = -\frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial \boldsymbol{\pi}' \partial \boldsymbol{\pi}'^T} = - \begin{bmatrix} \frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial^2 \pi_1} & \frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial \pi_1 \partial \pi_2} & \cdots & \frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial \pi_1 \partial \pi_{m-1}} \\ \vdots & \vdots & & \vdots \\ \frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial \pi_{m-1} \partial \pi_1} & \frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial \pi_{m-1} \partial \pi_2} & \cdots & \frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial^2 \pi_{m-1}} \end{bmatrix}$$

where

$$\frac{\partial \ell(\boldsymbol{\pi}_\times)}{\partial \pi_k} = \sum_{i=1}^{n} \frac{f_{ik} - f_{im}}{\sum_{j=1}^{m} \pi_j f_{ij}} \qquad \text{and} \qquad \frac{\partial^2 \ell(\boldsymbol{\pi}_\times)}{\partial \pi_k \partial \pi_r} = -\sum_{i=1}^{n} \frac{(f_{ik} - f_{im})(f_{ir} - f_{im})}{(\sum_{j=1}^{g} \pi_j f_{ij})^2}$$

The observed information derived covariance matrix of $\boldsymbol{\pi}_\times$ yields the following estimates for covariance and correlation for all m estimated weights in $\hat{\boldsymbol{\pi}}$:

$$\operatorname{Cov}(\hat{\pi}_p, \hat{\pi}_q) = \begin{cases} \left[I^{-1}(\hat{\boldsymbol{\pi}}_\times) \right]_{pq} & p, q < m \\ -\sum_{j=1}^{m-1} \operatorname{Cov}(\hat{\pi}_j, \hat{\pi}_q) & p = m, q < m \\ \sum_{j=1}^{m-1} \sum_{k=1}^{m-1} \operatorname{Cov}(\hat{\pi}_j, \hat{\pi}_q) & p, q = m \end{cases}$$

$$\operatorname{Var}(\hat{\pi}_j) = \sigma_j^2 = \left\{ \operatorname{Cov}(\hat{\boldsymbol{\pi}}) \right\}_{jj}$$

$$\operatorname{Corr}(\hat{\pi}_p, \hat{\pi}_q) = \frac{\operatorname{Cov}(\hat{\pi}_p, \hat{\pi}_q)}{\sqrt{\sigma_p^2 \sigma_q^2}}$$

$$\text{Z-score} = \frac{\hat{\pi}_j - \pi}{\sigma_{\hat{\pi}_j}}$$

Figure 1. Left: correlation where size of sphere represents correlation value, and opacity of sphere represents $\pi_q + \pi_p$. Right: correlation where size of sphere represents $\pi_q + \pi_p$ and opacity represents correlation. Top plots ignore sign of correlation; bottom ones color negative correlation orange.

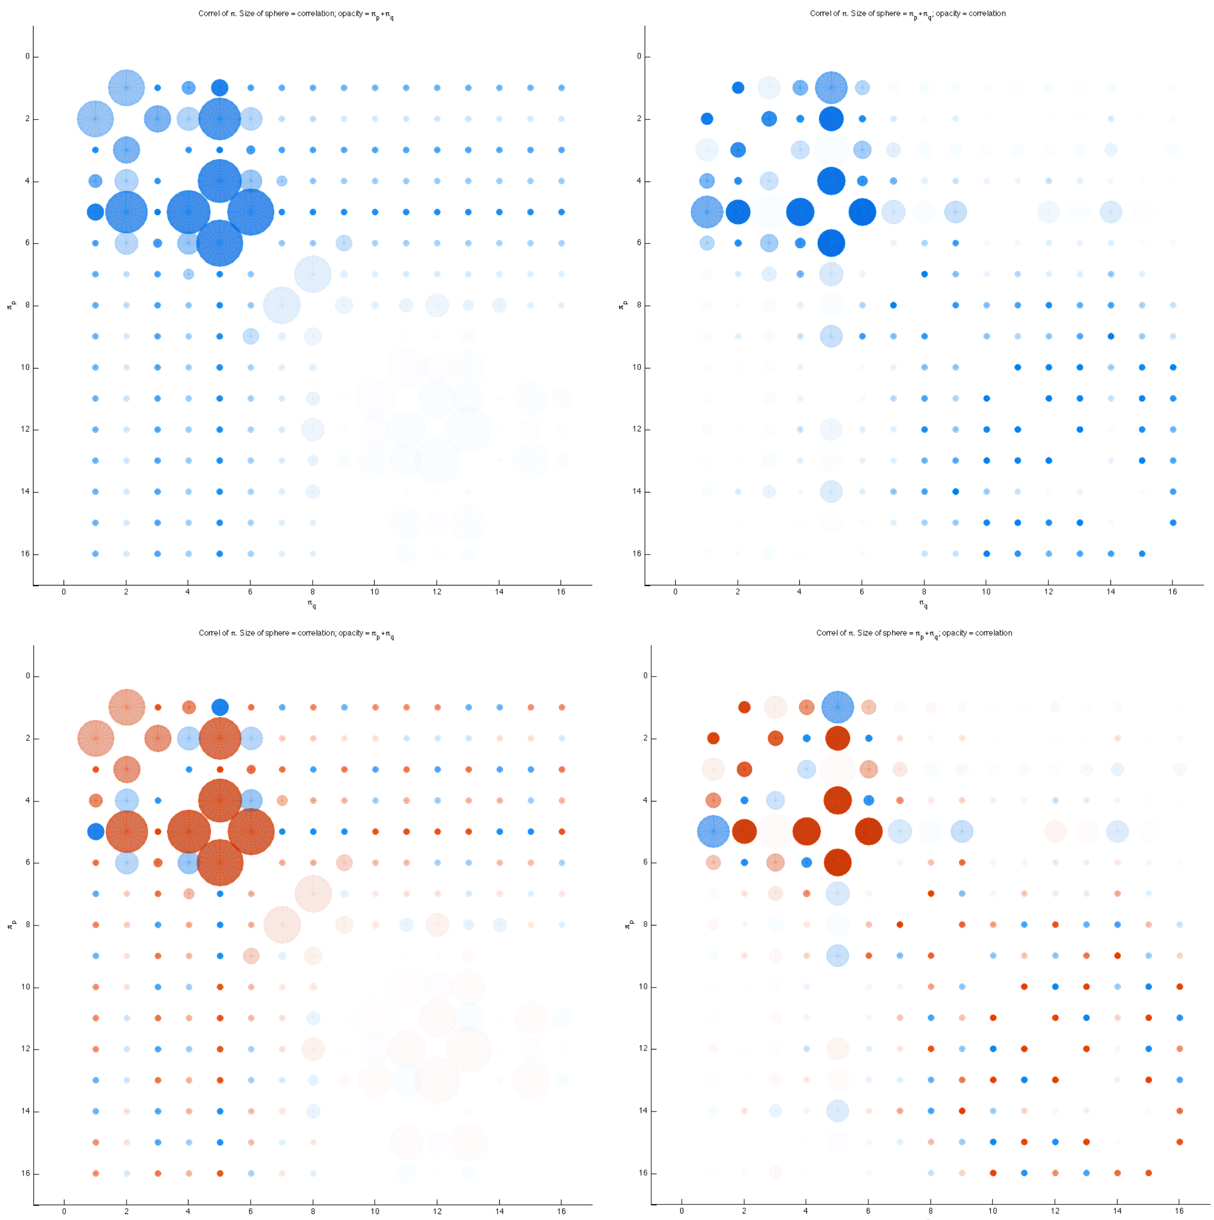

FIGURE 2. Left: standard deviation of each π_j. Right: Z-score, with 1 and 2 standard deviations marked as dotted lines. Colors are same as EM diagnostic plots. Size represents the value of π_j.

4. Likelihood ratio test

Given certain conditions

$$H_0 : \boldsymbol{\pi} = \boldsymbol{\pi}_{\text{true}}$$
$$H_1 : \boldsymbol{\pi} \neq \boldsymbol{\pi}_{\text{true}}$$

$$\Lambda = -2 \log \frac{\sup_{\boldsymbol{\pi}=\boldsymbol{\pi}_{\text{true}}} \ell(\boldsymbol{\pi})}{\sup_{\boldsymbol{\pi}} \ell(\boldsymbol{\pi})} = -2\{l(\boldsymbol{\pi}_{\text{true}}) - l(\hat{\boldsymbol{\pi}})\} \sim \chi^2_{m-1}$$

$$\begin{aligned} \Lambda_{\text{Halo 3}} &= 25.025 \sim \chi^2_{15} \\ \text{p-value 10k} &= 4.961\% \\ \text{p-value 30k} &= 1.3 \times 10^{-5}\% \\ \text{p-value 50k} &= 1.4 \times 10^{-12}\% \end{aligned}$$

Thus we accept H_0 when requiring 95% or less confidence; there is only a 4.961% chance we would see a value this extreme or more given H_0 is true. This holds for 400 to 1600 EM iterations.
